(Received 11 March 2010; published 9 February 2011)

We describe a new regime of magnetotransport in two-dimensional electron systems in the presence of a narrow potential barrier. In such systems, the Landau level states, which are confined to the barrier region in strong magnetic fields, undergo a deconfinement transition as the field is lowered. Transport measurements on a top-gated graphene device are presented. Shubnikov–de Haas (SdH) oscillations, observed in the unipolar regime, are found to abruptly disappear when the strength of the magnetic field is reduced below a certain critical value. This behavior is explained by a semiclassical analysis of the transformation of closed cyclotron orbits into open, deconfined trajectories.

Electron cyclotron motion constrained by crystal boundaries displays interesting phenomena, such as skipping orbits and electron focusing, which yield a wealth of information on scattering mechanisms in solids [1,2]. Since the 1980s, semiconducting two-dimensional electron systems have become a vehicle for investigating the interplay between gate-induced potential and cyclotron motion. A variety of interesting phenomena was explored in these systems, including quenching of the quantum Hall effect [3,4], Weiss oscillations due to commensurability between cyclotron orbits and a periodic grating [5], pinball-like dynamics in 2D arrays of scatterers [6], and coherent electron focusing [7].

The experimental realization of graphene [8], a new high-mobility electron system, affords new opportunities to explore effects that were previously inaccessible. Here we focus on one such phenomenon, the transformation of the discrete Landau level spectrum to a continuum of extended states in the presence of a static electric field. Previous attempts to induce sharp potential barriers in III-V semiconductor structures have been limited by the depth at which the two-dimensional electron system is buried—typically about 100 nm below the surface [9]. In contrast, electronic states in graphene, a truly two-dimensional material, are fully exposed and thus allow for potential modulation on ~10 nm length scales using small local gates and thin dielectric layers [10–13].

To probe the phenomena of interest, barrier widths must be comparable to the magnetic length \( \ell_B = (\hbar c/eB)^{1/2} \). This condition gives characteristic fields as low as 30 mT for systems such as GaAs. Magnetic oscillations are nearly washed out at such fields, making the effects described below hard to probe in GaAs structures. In contrast, the gate widths available in graphene translate to much higher fields of a few tesla, making graphene the system of choice for this experiment.

The behavior of interest is illustrated by a toy model involving the Landau levels of a massive charged particle in the presence of an inverted parabolic potential \( U(x) = -ax^2 \), which is uniform along the \( y \) direction. Competition between the repulsive potential and magnetic confinement gives rise to a modified harmonic oscillator spectrum

\[
e_n(p_y) = \frac{\hbar e}{m} \sqrt{B^2 - B_c^2(n + 1/2)} - \frac{2ap_y^2}{e^2(B^2 - B_c^2)} \]

for \( B > B_c \), where \( m \) is the particle mass, \( p_y \) is the \( y \) component of momentum, and \( B_c = \sqrt{2ma/e} \) is the critical magnetic field strength. For strong magnetic field, \( B > B_c \), the spectrum consists of discrete (but dispersive) energy bands indexed by an integer \( n \), whereas for \( B \leq B_c \), the spectrum is continuous even for fixed \( p_y \). This behavior can be understood quasiclassically in terms of transformation of closed cyclotron orbits into open orbits, which occurs when the Lorentz force is overwhelmed by the repulsive barrier potential.

Landau levels of massless Dirac charge carriers subject to a linear potential \( U(x) = -eEx \) exhibit an analogous collapse of the discrete spectrum [14]:

\[
e_n(p_y) = \pm v_F \sqrt{2n\hbar eB(1 - \beta^2)^{3/4}} - \beta v_F p_y, \]

where \( n = 0, 1, 2, \ldots \) and \( \beta = E/v_F \). The transition at \( B_c = E/v_F \) can be linked to the classical dynamics of a massless particle, characterized by closed orbits at \( B > B_c \) and open trajectories at \( B < B_c \) [15].

A simple picture of the spectrum (2) can be obtained from the Bohr-Sommerfeld quantization condition

\[
\int_{x_1}^{x_2} p_y(x) dx = \pi \hbar (n + \gamma),
\]

where \( x_1 \) and \( x_2 \) are the turning points, \( \gamma = 0 \) due to the Berry phase contribution for Dirac fermions, and

\[
p_y(x) = \sqrt{[e - U(x)]^2/v_F^2 - (p_y - eEx)^2}.
\]

For linear \( U(x) \), this gives the Landau level spectrum (2) for \( B > B_c \). As \( B \) approaches \( B_c \), one of the turning points
moves to infinity, indicating a transformation of closed orbits into open trajectories.

To realize the collapse of Landau levels in an electron system, several conditions must be met. First, it must be possible to create a potential barrier that is steep on the scale of the cyclotron orbit radius. Second, the system must be ballistic on this length scale in order to suppress the broadening of Landau levels due to disorder. Graphene fulfills both conditions. As demonstrated by the recent observation of Fabry-Perot (FP) oscillations in gated graphene structures [13], transport can remain ballistic even in the presence of a gate-induced barrier. Thus graphene is an ideal system for studying the Landau level collapse.

Transport data taken from a locally gated device similar to that described in Ref. [13] are shown in Fig. 1. Graphene was prepared via mechanical exfoliation and contacted using electron beam lithography before being coated with a 7/10 nm thick hydrogen silsesquioxane/HfO$_2$ dielectric layer. Narrow ( ~ 16 nm) palladium top gates were then deposited, and the electrical resistance measured at 1.6 K. Finite element modeling [13] yields the density profile

\[ \rho(x) = \frac{C_{Vg} V_{tg}}{1 + x^2/w^2} + C_{bg} V_{bg}, \]  

(5)

with \( w = 50 \text{ nm} \), where \( C_{Vg(bg)} \) and \( V_{tg(bg)} \) are the top (bottom) gate capacitance and applied voltage. To eliminate the contribution of the series resistances of the graphene leads, the numerical derivative of the conductance with respect to the top gate voltage, \( dG/dV_{tg} \), was analyzed.

At zero magnetic field [Fig. 1(a)], \( dG/dV_{tg} \) shows distinct behavior in four regions in the \((V_{bg}, V_{tg})\) plane, corresponding to \( pp'p, npn, npn \), and \( mm'n \) doping, where \( n \) (\( p \)) refers to negative (positive) charge density and prime indicates different density. The appearance of FP interference fringes when the polarity of charge carriers in the locally gated region and graphene leads have opposite signs indicates that the mean free path is comparable to the barrier width, \( l_{mf} \sim w \).

In high magnetic field, a fan of SdH resonances corresponding to Landau levels is seen in both the bipolar and unipolar regimes [see Fig. 1(b)]. At lower fields, the observed behavior depends on the polarity under the gate. In the bipolar regime, as \( B \) is lowered, the SdH resonances smoothly evolve into FP resonances. The half-period shift, clearly visible in the data at \( B = 1 \text{ T} \), is a hallmark of Klein scattering [16]. In the unipolar regime, the SdH resonances bend, becoming more horizontal at lower field. The oscillations first begin to lose contrast, and then completely disappear below \( B_c \approx 4 \text{ T} \) (Fig. 2).

The connection between this behavior and Landau level collapse is exhibited most clearly by a semiclassical analysis. The SdH resonances arise from an oscillatory contribution to the density of states at the Fermi level due to closed trajectories; the Bohr-Sommerfeld condition

\[ \int_{\epsilon_F}^{\epsilon} \frac{dV}{dot} \]  

(3) with \( \epsilon = \epsilon_F \) and \( p_x = 0 \) gives a good estimate for the positions of those resonances. For a generic barrier potential, Eq. (3) can be written directly in terms of experimental control parameters. Using the Thomas-Fermi approximation, and ignoring the effects of “quantum capacitance”
and nonlinear screening [17], we define the position-dependent Fermi momentum \( k_F(x) = \sqrt{4\pi \rho(x) / g} \), where \( g = 4 \) is the spin-valley degeneracy. Substituting the relation \( \varepsilon - U(x) = h v_F k_F(x) \) into Eq. (4), we obtain

\[
\int_{x_1}^{x_2} \frac{4\pi}{g} \frac{h^2}{2} \rho(x) - (p_y - eBx)^2 dx = \pi \hbar (n + \gamma). \tag{6}
\]

Interestingly, and somewhat unexpectedly, the quantization condition assumes the same form for massless and massive carriers with \( g = 4 \) (monolayer and bilayer graphene); it would thus be trivially modified for GaAs quantum wells (\( g = 2 \) and \( \gamma = 1/2 \)).

A rough estimate for the critical field can be obtained by comparing the curvature of \( \rho(x) \) at \( x = 0 \) with the \( B^2 x^2 \) term in Eq. (6). Near the polarity reversal boundary \( C_{bg} V_{bg} + C_{tg} V_{tg} = 0 \) [white dashed line in Fig. 1(a)], using the device parameters \( C_{bg} = 115 \text{ aF}/\mu\text{m}^2 \), \( V_{bg} = -70 \text{ V}, \ w = 50 \text{ nm} \), we find \( B_c = (h/\epsilon w) \times (\pi C_{bg} V_{bg}/g)^{1/2} = 5.2 \text{ T} \).

The dependence of \( B_c \) on experimental control parameters \( V_{bg} \) and \( V_{tg} \) can be obtained by analyzing the turning points for the density profile (5). Setting \( p_y = 0 \) gives \( h k_F(x) = \pm eBx \). Solving this equation and equating the result to barrier half-width, \( x(t_2) = \pm w \), we obtain

\[
B_c = (h/\epsilon w) \sqrt{(2\pi/eg)(2C_{bg} V_{bg} + C_{tg} V_{tg})}. \tag{7}
\]

Both the value of \( B_c \) and its dependence on gate voltages matches the data quite well [red line in Fig. 1(b)].

The actual density profile is nonparabolic, flattening outside the top gate region (TGR) on a length scale \( 2w = 100 \text{ nm} \). Yet, since the magnetic length \( \ell_B \) is much shorter than \( 2w \) for the fields of interest \((B \gtrsim 1 \text{ T})\), this flattening does not significantly impact our discussion of the collapse phenomenon. While the states realized at subcritical magnetic fields are not truly deconfined due to cyclotron motion in the region outside the TGR, the corresponding orbits are very long. For such states, the particle traverses the TGR, makes a partial cyclotron orbit outside of the TGR, and finally crosses the TGR again to close the orbit [Fig. 3(a)]. The net orbit length is a few \( w \), which is much greater than the orbit size at strong fields (a few \( \ell_B \)). The contribution of long orbits to SdH oscillations will be suppressed due to spatial inhomogeneity and disorder scattering; hence the distinction between confined and deconfined orbits remains sharp despite the flattening of the potential (also, see a more detailed discussion in the online supplement [18]).

With that in mind, below we analyze a simple model, \( U(x) = -ax^2 \). A simple estimate of the collapse threshold can be obtained by considering balance between the Lorentz force and the force due to the electric field, \( \nu_F B = -dU/dx \). This condition is satisfied for a particle moving parallel to the barrier with \( x = \pm \ell, \ \ell = \epsilon v_F B/(2a) \). This gives an energy-dependent critical field.

\[
B_c(e) = (2/ev_F)\sqrt{-ae}, \tag{8}
\]

which increases with detuning from neutrality, as in experiment.

We treat the problem using the microscopic Hamiltonian

\[
H = \begin{pmatrix} U(x) & \nu_F p_y \\ \nu_F p_x & U(x) \end{pmatrix}, \quad p_x = -i\hbar \frac{d}{dx} \pm \nu_F \phi_y, \tag{9}
\]

where \( \phi_y = p_y - Bx \) and \( p_x \) is the conserved canonical momentum component parallel to the barrier. We nondimensionalize the problem using “natural units”

\[
e_x = (\hbar^2 v_F^2 a)^{1/3}, \quad x_0 = \left( \frac{v_F \hbar}{a} \right)^{1/3}, \quad B_0 = \frac{h}{\epsilon v_F^2 h^{2/3}}. \tag{11}
\]

For each value of \( p_y \) and magnetic field \( B \), we represent the Hamiltonian as an \( M \times M \) matrix defined on a grid in position space, with periodic boundary conditions. We use the eigenvalues and eigenstates obtained from diagonalization to evaluate the local density of states (DOS) in the middle of the barrier,

\[
N(\epsilon) = \int dp_y \sum_{n=1}^{M} \frac{1}{\pi} \frac{\Gamma}{(\epsilon - \epsilon_n)^2 + \Gamma^2}, \tag{10}
\]

with Landau level broadening incorporated through the Lorentzian width \( \Gamma = 0.2 \epsilon_n \). In our simulation, a system of size \( L = 15x_0 \) discretized with \( M = 1500 \) points was used. Averaging with a Gaussian weight was used to suppress the effect of spurious states arising due to a vector potential jump at the boundary,

\[
\langle |\psi_{n,p_y}(x = 0)|^2 \rangle = \int dx' e^{-x'^2/2\sigma^2} |\psi_{n,p_y}(x')|^2, \tag{11}
\]

with \( \sigma = x_0 \). Oscillations in the density of states (10) modulate the rate of electron scattering by disorder, and
thus show up in transport quantities measured as a function of experimental control parameters, as in the canonical SdH effect [19].

The resulting local DOS exhibits oscillations which track Landau levels at high $B$ [Fig. 1(d)]. In the $pp/p$ case, at lower $B$, discrete Landau levels give way to a continuous spectrum in the region inside a parabola (dashed line) which marks the collapse threshold, Eq. (8).

The DOS exhibits FP fringes in the $ppn$ region at low $B$, however without the half-period shift seen in $dG/dV_{bg}$ at $B \approx 1 \text{T}$ (Fig. 1). As discussed in Ref. [16], this half-period shift results from FP interference due to Klein scattering at $p$ interfaces. A proper model of this effect must account for ballistic transport in the system.

The collapse observed in the density of states is related to deconfinement of classical orbits. The orbits can be analyzed as constant energy trajectories of the problem

$$\epsilon = v_F \sqrt{p_x^2 + p_y^2} + U(x), \quad \vec{p}_y = p_y - eBx. \quad (12)$$

For parabolic $U(x) = -ax^2$ the orbits with $p_y = 0$ can be easily found in polar coordinates $p_x + i\vec{p}_y = |p|e^{i\theta}$;

$$|p| = \frac{1}{\sin^2 \theta} \left(1 \pm \frac{1}{\epsilon_c} \sin^2 \theta\right), \quad \epsilon_c = \frac{(v_F eB)^2}{4a} \quad (13)$$

with $p_0 = v_F e^2 B^2 / 2a$ [see Fig. 3(b)]. Only real, positive solutions should be retained; when $\epsilon/\epsilon_c > 1$, the discriminant in Eq. (13) is negative near $\theta = \pi/2$ and trajectories cannot close [blue (dark gray) curves in Fig. 3(b)].

The related orbits in position space can be found from the relation $dy/dx = \dot{y}/\dot{x} = p_y/p_x$, giving

$$\frac{dy}{dx} = \frac{\pm v_F (p_y - eBx)}{\sqrt{(\epsilon - U(x))^2 - v_F^2 (p_y - eBx)^2}}. \quad (14)$$

For $p_y = 0$, we integrate Eq. (14) to obtain $y = \pm \ell \int [(u + \epsilon/\epsilon_c - 2)^2 + 4(\epsilon/\epsilon_c - 1)]^{1/2} du$, where $u = x^2/\ell^2$, $\ell = v_F eB / 2a$ such that $\epsilon_c = a\ell^2$. The integrand changes its behavior at the critical energy $\epsilon_c$. For $\epsilon > \epsilon_c$, the integrand is real valued for all $u$ and

$$\sinh \left( \frac{y(x) - y_0}{\ell} \right) = \frac{x^2/\ell^2 + \epsilon/\epsilon_c - 2}{2\sqrt{\epsilon_c - 1}} \quad (15).$$

For $\epsilon < \epsilon_c$, real solutions are divided into two domains $0 \leq u \leq 2 - \epsilon/\epsilon_c - 2\sqrt{1 - \epsilon/\epsilon_c}$ (closed orbits) and $u > 2 - \epsilon/\epsilon_c + 2\sqrt{1 - \epsilon/\epsilon_c}$ (open orbits):

$$\cosh \left( \frac{y(x) - y_0}{\ell} \right) = \pm \frac{2 - \epsilon/\epsilon_c - x^2/\ell^2}{2\sqrt{\epsilon_c - 1}} \quad (16).$$

The red (medium gray) curves in Fig. 3(c) correspond to the low energy regime, $\epsilon < \epsilon_c$, where orbits can either be closed (Landau levels) or open (trajectories for particles moving far from the barrier). At higher energies, $\epsilon > \epsilon_c$, all trajectories are open. The straight black lines correspond to the critical orbits of Eq. (8), where the Lorentz force and electric field are balanced. In addition to the two particular critical trajectories shown, in the limit $\epsilon/\epsilon_c \rightarrow 1$ there is an entire family of critical trajectories which asymptotically approach these lines.

Interestingly, unlike in the case of the potential obtained from the Thomas-Fermi model, where the classical turning points move continuously to infinity as the transition is approached, trajectories in the parabolic potential are trapped between the critical separatrix lines. At very low energies, closed orbits are approximately circular; as the energy increases towards $\epsilon_c$, orbits become more and more elongated, until finally merging with the separatrix at $\epsilon = \epsilon_c$ (see Fig. 3).

In summary, graphene devices with a barrier induced by a narrow top gate can be used to probe electronic states on the spatial scale of a few tens of nanometers. In our transport measurements, the SdH-type resonances arising from quantized states associated with closed orbits are used to directly observe the competition between magnetic confinement and deconfinement due to electric field. As a result of this competition, the discrete spectrum of Landau levels collapses when subjected to a strong external potential. Experimental observations are found to be in good agreement with theory.
